

CO₂ Electrolysis with High Conversion Fraction for CO Utilization and Energy Efficiency

Michael Hecht, Parker Steen, Jeffrey Hoffman, and Mike Horn

or
5 minutes of terror!

Solid oxide electrolysis for MOXIE...

Why we want high conversion fraction (F_c)

- ◆ The MOXIE reaction is $2\text{CO}_2 \rightarrow 2\text{CO} + \text{O}_2$
 - MOXIE typically converted ~30% of the CO_2 it took in to $\text{CO} + \text{O}_2$
- ◆ The compressor uses a lot of power to collect all that CO_2 !
- ◆ If we want to use the CO as fuel, or to make fuel, it needs to be purer
- ◆ For Venus balloon, we need at least 75% CO for buoyancy

High Conversion Fraction (F_c)

- ◆ Why we didn't do it
 - Not a requirement!
 - Not a metric!
 - Not easy!
 - Not safe!
- ◆ What we can control
 - Supply voltage or Current (CO , O_2 rate)
 - Flow (CO_2 rate)
- ◆ What we can't control
 - Stack resistance ($i\text{ASR}$)

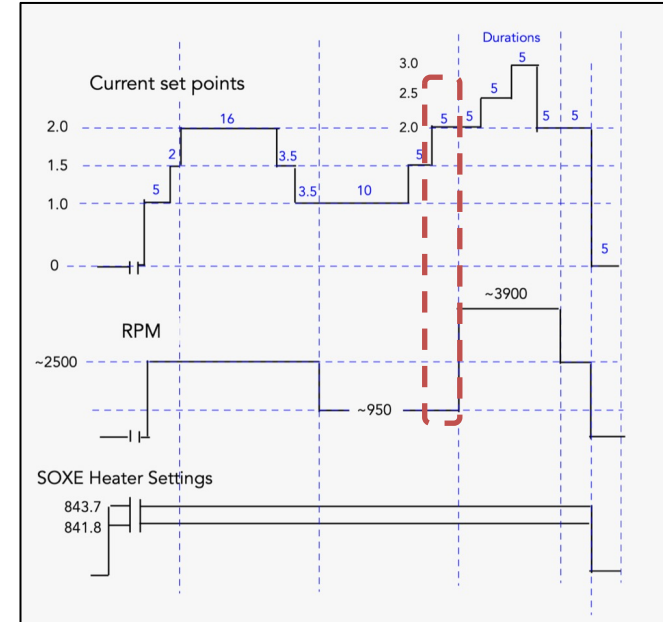

Current at fixed cell voltage vs conversion fraction

CO₂ conversion fraction (MOXIE on Mars)

What's going on with FMOC-22?

Purpose: Testing low pressure SOE, fixed current steps
(Also low flow, since flow and pressure are proportional on the FM)

Positive impact on power usage!

Typical power allocation for a MOXIE run.

How close to $V_N(C)$ did we come?

EMOC-18 (lab precursor) for comparison

Cell Voltage

Conversion Fraction

What's going on with the bottom stack?

EMOC-18

FMOC-22

Error bars

- There must be coking in the bottom stack!
- But why does that make the voltage *better*?

Apparently no harm done (it wouldn't be expected in 3 minutes)

The voltage *dropped* when carbon was being deposited. Why?

- ◆ We often see a characteristic thermal time constant of 10-15 minutes for *the stack as a whole*.
- ◆ We've seen an apparent fast response when we change flow
- ◆ We postulate a similar fast response when the *exothermic* $2\text{CO} \rightarrow 2\text{C} + \text{O}_2$ reaction kicks in!
 - Higher temperature \rightarrow lower ASR \rightarrow lower voltage
 - Fortuitously, this should limit the coking and prevent runaway
- ◆ Eventually, overall stack degradation from carbon deposition would take over and voltage would go up.

We demonstrated that:

- ◆ MOXIE can operate at close to 90% conversion efficiency
- ◆ At low pressure and high efficiency the compressor power drops to a fraction of the electrochemical power
- ◆ A few minutes of carbon deposition does no significant harm, in part because it warms the cell and limits the reaction
- ◆ $V_N(C)$ can be recognized by a characteristic signature – a substantial advantage for planning safe operations.

Venus: Lab experiment at 0.5 bar

At least 75% CO needed for buoyancy

We manually stepped down the flow to enhance F_c

Note ~20% drop in O₂ production, from 4.2 to 3.3 g/hr

- ◆ Under Venus conditions we sustained 75% conversion efficiency for 90 minutes on a degraded stack.
- ◆ Oxygen output drops by ~20% as inlet flow is reduced, from 4.2 to 3.3 g/hr.
 - This isn't the whole story. MOXIE has achieved 12 g/hr with much higher flow.
- ◆ Easy to compensate by adding more cell area; payoff is much better power efficiency
